Roy Chin**

Background of the Invention

The present invention relates to apparatus and methods for ablating biological tissues. More particularly, the present invention relates to improved ablation devices that are capable of penetrating through bodily organs.

Since their introduction at the end of the 80's, medical ablation devices have become a standard tool for surgeons and electrophysiologists. For example, ablation devices utilizing DC shock, radio frequency (RF) current, ultrasound, microwave , direct heat, cryotherapy or lasers have been introduced and employed to various degrees to ablate biological tissues. In some ablation procedures, however, the ablation of the targeted tissues may be difficult because of their location or the presence of physiological obstacle. For example, in some coronary applications where the ablation lines are done epicardially, the epicardium may be covered by layers of fat that can prohibit the lesion formation in the myocardial tissue.

Catheter devices are commonly used to perform the ablation procedure. They are generally inserted into a major vein or artery or through a bodily cavity such as the mouth, urethra, or rectum. These catheters are then guided to a targeted location in the body (e.g., organ) by manipulating the catheter from the insertion point or the natural body's orifice. By way of example, in coronary applications, a catheter is typically inserted tranvenously in the femoral vein and guided to a cardiac chamber to ablate myocardial tissues. Although catheters work well for a number of

applications, in many applications it would be desirable to provide an ablation assembly that can be used to position an ablation device during a surgical procedure.

Summary of the Invention

To achieve the foregoing and other objects of the invention, methods and devices pertaining to the ablation of tissues inside the cavity of an organ are disclosed. In general, the invention pertains to an ablation assembly, and more particularly to a surgical device, which includes an ablative energy source and an ablative energy delivery device coupled to the ablative energy source. The ablative energy delivery device is configured for delivering ablative energy sufficiently strong to cause tissue ablation. In most embodiments, the ablative energy is formed from electromagnetic energy in the microwave frequency range.

The invention relates, in one embodiment, to an ablation assembly that includes an ablation tool, which has a distal portion configured for delivering ablative energy sufficiently strong to cause tissue ablation, and a probe, which has a needle shaft with a lumen extending therethrough. The needle shaft also has a proximal access end and a distal penetration end that is adapted to penetrate through a wall of an organ to an organ cavity. The lumen is arranged for slidably carrying the ablation tool from an un-deployed position, which places the distal portion of the ablation tool inside the lumen of the needle shaft, to a deployed position, which places the distal portion of the ablation tool past the distal penetration end of the needle shaft.

In some embodiments, the distal portion of the ablation tool is arranged to lie at an angle relative to a longitudinal axis of the probe when the distal portion of the ablation tool is deployed past the distal penetration end of the needle shaft. By way of example, an angle of between about 45 to about 135 degrees may be used. In related embodiments, the ablation assembly includes an angular component for directing the distal portion of the ablation tool to a predetermined angular position. By way of example, a steering arrangement, a biasing arrangement or a curved probe arrangement may be used.

The invention relates, in another embodiment, to an ablation assembly that includes a probe, an antenna and a transmission line. The probe is adapted to be inserted into a body cavity and to penetrate an organ within the body cavity. The probe also has a longitudinal axis. The antenna is carried by the probe for insertion

into a cavity within the organ, and the transmission line is carried by the probe for delivering electromagnetic energy to the antenna. Furthermore, the antenna and transmission line are arranged such that when the antenna is deployed into the organ cavity, the antenna lies at an angle relative to the longitudinal axis of the probe. In some embodiments, when the antenna is deployed into the organ cavity, the antenna lies proximate and substantially parallel to the inner wall of the organ.

The invention relates, in another embodiment, to a microwave ablation assembly that includes an elongated probe, a transmission line and antenna device. The probe has a penetration end adapted to penetrate into an organ and an opposite access end. The probe also has a longitudinal axis and defines an insert passage extending therethrough from the access end to the penetration end thereof. The transmission line is arranged for delivering microwave energy, and has a proximal end coupled to a microwave energy source. The antenna device is distally coupled to the transmission line, and is arranged for radiating a microwave field sufficiently strong to cause tissue ablation. The antenna device further includes an antenna and a dielectric material medium disposed around the antenna. Furthermore, the antenna device and at least a portion of the transmission line are each dimensioned for sliding receipt through the insert passage of the elongated probe, while the elongated probe is positioned in the organ, to a position advancing the antenna device past the penetration end of the probe and at an angle relative to the longitudinal axis of the probe.

In some embodiments, the transmission line is a coaxial cable that includes an inner conductor, an outer conductor, and a dielectric medium disposed between the inner and outer conductors. In a related embodiment, a distal portion of the outer conductor is arranged to be exposed inside the cavity of the organ. In another related embodiment, the ablation assembly further includes a ground plane configured for coupling electromagnetic energy between the antenna and the ground plane. The ground plane is generally coupled to the outer conductor of the transmission line and is positioned on the transmission line such that when the antenna is advanced into the organ cavity proximate the inner wall of the organ, the ground plane is disposed outside the organ cavity proximate the outer wall of the organ.

The invention relates, in another embodiment, to a method for ablating an inner wall of an organ. The method includes providing a surgical device that includes a probe and an ablation tool. The probe is adapted to be inserted into a body cavity and to penetrate an organ within the body cavity. The probe also has a longitudinal axis. The ablation tool, which has a distal portion for delivering ablative energy, is carried by the probe for insertion into a cavity within the organ. The method further includes introducing the surgical device into a body cavity. The method additionally includes penetrating a wall of the organ with the probe. The method also includes advancing the probe through the wall of the organ and into an interior chamber thereof. The method further includes deploying the distal portion of the ablation tool inside the interior chamber of the organ at an angle relative to the longitudinal axis of the probe, wherein the distal antenna is positioned proximate an inner wall of the organ. Moreover, the method includes delivering ablative energy that is sufficiently strong to cause tissue ablation.

In most embodiments, the organ, which is being ablated, is the heart. As such, the ablation assembly may be used to create lesions along the inner wall of the heart. By way of example, these lesions may be used treat atrial fibrillation, typical atrial flutter or atypical atrial flutter.

The invention relates, in another embodiment, to an ablation assembly that includes a needle antenna and a transmission line. Both the needle antenna and the transmission line are adapted to be inserted into a body cavity. The transmission line is arranged for delivering electromagnetic energy to the needle antenna, and includes a longitudinal axis. The needle antenna is arranged for transmitting electromagnetic energy that is sufficiently strong to cause tissue ablation. The needle antenna is also includes a penetration end adapted to penetrate an organ within the body cavity such that the needle antenna can be advanced through a wall of the organ into a cavity within the organ. Furthermore, at least one of the needle antenna or the transmission line is bent at an angle relative to the longitudinal axis of the transmission line so that the needle antenna can be positioned proximate an inner wall of the organ.

The invention relates, in another embodiment, to a method for ablating an inner wall of an organ. The method includes providing a surgical device that has a

needle antenna distally coupled to a transmission line. The transmission line has a longitudinal axis, and the needle antenna has a distal penetration end that is adapted to penetrate through a wall of an organ. The needle antenna is also adapted for delivering electromagnetic energy. Furthermore, at least one of the needle antenna or the transmission line is bent at an angle relative to the longitudinal axis of the transmission line. The method further includes introducing the surgical device into a body cavity. The method additionally includes penetrating a wall of the organ with the distal penetration end of the needle antenna. The method also includes advancing the needle antenna through the wall of the organ and into an interior chamber thereof. The method further includes positioning the needle antenna inside the interior chamber of the organ such that the needle antenna is proximate an inner wall of the organ. Moreover, the method includes radiating electromagnetic energy that is sufficiently strong to cause tissue ablation.

Detailed Description of Preferred Embodiments

The present invention will now be described in detail with reference to a few preferred embodiments thereof and as illustrated in the accompanying drawings. In the following description, numerous specific details are set forth in order to provide a thorough understanding of the present invention. It will be apparent, however, to one skilled in the art, that the present invention may be practiced without some or all of these specific details. In other instances, well known process steps have not been described in detail in order not to unnecessarily obscure the present invention.

The present invention provides an ablation assembly that is capable of ablating tissues inside the cavity of an organ (or duct). More specifically, the present invention provides an ablation assembly that is capable of producing lesions along an interior wall of an organ. The ablation assembly generally includes an ablative energy source and an ablative energy delivery device coupled to the ablative energy source. The ablative energy delivery device is configured for delivering ablative energy sufficiently strong to cause tissue ablation. The ablative energy delivery device generally includes an angular component that is used to position the device inside the organ after the device has been inserted through the wall of the organ. In one embodiment, a probe (or introducer), which has a penetration end adapted to penetrate through a wall of an organ, is used to help insert (or introduce) the device through the wall of the organ. In another embodiment, the device itself is arranged to include a penetration end that is adapted to penetrate through a wall of an organ.

In accordance with one embodiment of the present invention, the ablation assembly includes a probe and an ablation tool. The ablation tool, which includes an antenna and a transmission line coupled to the antenna, is adapted to be carried by the probe for insertion within a cavity inside the organ. The transmission line is arranged for delivering electromagnetic energy to the antenna. The probe is adapted to be inserted into a body cavity and to penetrate an organ within the body cavity. Furthermore, the ablation assembly is arranged so that when the antenna is deployed into the organ cavity, the antenna lies at an angle relative to the longitudinal axis of the probe. In some embodiments, upon deployment, the antenna is configured to

assume a predetermined position that substantially matches the shape and/or angular position of the wall to be ablated.

Referring initially to Figs. 1-3, an ablation assembly in accordance with one embodiment of the invention will be described. In this embodiment, the ablation assembly, generally designated 10 (illustrated in Fig. 3), includes a relatively thin, elongated probe 12 (illustrated in Fig. 1), which works in combination with an ablation tool 24 (illustrated in Fig. 2). The probe 12 has a proximal access end 14 and an opposite distal penetration end 16 adapted to penetrate an organ 18 within a body cavity 20. The probe 12 also has a longitudinally extending lumen 22 that is sized suitably for receiving the ablation tool 24 therethrough. The ablation tool 24 includes a transmission line 28 that carries an antenna device 30 at its distal end. The antenna device 30 is designed to generate an electromagnetic field sufficiently strong to cause tissue ablation. A proximal end 42 of the transmission line 28 is coupled to an energy source (not shown).

The antenna device 30 and the transmission line 28 are sized such that they are slidable through the lumen 22 while the elongated probe 12 is positioned in a wall 35 of the organ 18. As such, the ablation tool 24 may be advanced within the probe 12 until the antenna device 30 is moved into a cavity within the organ 18 at a position beyond the penetration end 16 of the probe 12. As shown in Fig. 3B, the ablation tool 24 is configured so that when it is extended beyond the penetration end 16 of the probe 12, the antenna 30 lies at an angle 38 relative to the longitudinal axis 40 of the probe 12 (the axis taken from the proximal end 14 of the probe). In many embodiments, the angle 38 is arranged such that when the antenna device 30 is deployed into the organ cavity, the antenna device 30 assumes a predetermined angular position that matches the shape and/or angular position of the wall to be ablated. By way of example, an angular position that places the antenna device substantially parallel to the cavity wall may be used.

Accordingly, an ablation assembly is provided which utilizes a thin, elongated probe as a deployment mechanism to position an antenna device within the organ targeted for ablation. Once the probe is positioned in a wall of the organ, the antenna device and the transmission line are inserted through the passage of the probe as a unit

until the antenna device is positioned inside the cavity of the organ. Subsequently, an electromagnetic field is emitted from the antenna device that is sufficiently strong to cause tissue ablation. This arrangement is especially beneficial when the areas targeted for ablation have obstructions along the outer wall of the organ. For example, the ablation assembly may be used to bypass and navigate around layers of fat or veins that surround the epicardial surface (e.g., outer wall) of the heart. Additionally, the angular component of the ablation assembly allows precise positioning and placement of the antenna device at specific locations within the cavity of a bodily organ. As a result, the ablative energy can be accurately transmitted towards the tissue targeted for ablation.

Referring to Figs. 3A & 3B, the elongated probe 12 includes a rigid needle 43 having an elongated needle shaft 44 adapted to pierce through the organ 18 at its distal penetration end 16. By way of example, the distal penetration end 16 may take the form of a conventional beveled tipped needle or a beveled point chamfered needle both of which form a sharp cutting edge. The lumen 22 extends longitudinally through the needle shaft 44, and includes a proximal access opening 46 and an opposite distal penetration opening 47 at the distal penetration end 16 thereof. As shown, a handle 50 is disposed at the proximal end of the needle shaft 44 to help facilitate the insertion and extraction of the antenna device 30 into and out of the proximal access opening 46 of the lumen 22.

In general, the needle shaft 44 is a thin walled rigid tube having an outer diameter of about less than about 3 mm and an inner diameter of about less than 1.5 mm. In addition, a wall thickness in the range of between about 0.003 inches to about 0.007 inches, and a lumen diameter (inner diameter) in the range of about 0.040 inch to about 0.060 inch may be used. In the embodiment shown, the wall thickness is about 0.005 inches and the lumen diameter is about 0.050 inches. This relatively small diameter size is particularly suitable for use in highly vascularized organs, such as the heart, so as to minimize the puncture diameter and, thus, potential bleeding. It will be appreciated, of course, that the present invention may be utilized to ablate the tissues of other organs, and more particularly, the interior walls of other organs as well. Furthermore, the needle shaft may be formed from any suitable material that is rigid and bio-compatible. By way of example, stainless steel may be used.

Additionally, it should be noted that the sizes are not a limitation, and that the sizes may vary according to specific needs of each device.

In most embodiments, the probe is first positioned through the skin or a body cavity, and then into the targeted organ or tissues. Depending upon the depth of penetration, the wall of the penetrated organ surrounding the needle shaft may be employed to vertically and laterally position (and support) the probe during tissue ablation. Referring to Figs 3A and 3B, once the probe 12 is properly positioned and retained at the targeted penetration site, and more particularly once the distal penetration end 16 of the needle shaft 44 is placed at the proper selected depth (such as that shown in Figs. 3A & 3B), the antenna device 30 may be advanced into the organ cavity.

In some embodiments, the probe 12 and the ablation tool 24 are formed as an integral unit, wherein the antenna device 30 is moved into position by advancing the ablation tool 24 through the probe from a first predetermined position to a second predetermined position. For example, a handle, which is mechanically coupled to the ablation tool 24, may be used to control the sliding movement of the antenna tool 24 through the probe 12. As such, the first predetermined position is configured to place the antenna device 30 in an un-advanced position (as shown in Fig. 3A) and the second predetermined position is configured to place the antenna device 30 in a deployed position (as shown in Fig. 3B). In other embodiments, the probe 12 and the ablation tool 24 are separate elements and therefore the ablation tool 24 is inserted into the probe 12 after the probe 12 has been positioned in the targeted area of the organ 18. After ablation tool 24 has been inserted into the probe 12, the antenna device 30 can be advanced from the un-advanced position (as shown in Fig. 3A) to the deployed position (as shown in Fig. 3B).

During deployment, the ablation tool 24 is moved through the handle 50 and through the lumen 22. As best viewed in Figs. 3A & 3B the antenna device 30 and the associated transmission line 28 are advanced longitudinally through the lumen 22 of the needle shaft 44 to the distal penetration end 16 thereof. Upon subsequent advancement, the antenna device 30 may be manipulated to extend through the penetration opening 47 of the insert passage 22 and into the cavity of the organ 18.

Such advancement allows the antenna device 30 to assume a predetermined position having an angle 38 relative to the longitudinal axis 40 of the probe 12. As shown, the predetermined position is in a direction towards the inner wall of the organ 18, and substantially parallel to the tissue targeted for ablation thereof. In one embodiment, the antenna device is arranged to move into the angled position during advancement of the antenna tool through the probe. In another embodiment, the antenna device is arranged to move into the angled position after advancement of the antenna tool through the probe. Deployment techniques will be discussed in greater detail below.

As shown in Figs. 3A & 3B, the probe 12 is perpendicularly penetrating the organ 18, and the antenna device 30 is positioned about 90 degrees from the longitudinal axis 40 of the probe 12. It is contemplated, however, that this position is not always possible because some organs are particularly difficult to access, and therefore the probe 12 may be inserted into the wall of the organ 18 at different angles. Accordingly, the present invention may be configured to provide a range of angled positions to match the shape and/or angular position of the wall to be ablated. By way of example, an antenna device position having an angle in the range of between about 45 degrees to about 135 degrees may be used. To illustrate this, Fig. 4A shows the antenna device 30 in an acute angular position having an angle 38 of about 60 degrees relative to the longitudinal axis 40, and Fig. 4B shows the antenna device 30 in an obtuse angular position having an angle 38 of about 120 degrees relative to the longitudinal axis 40. These angular positions are important parameters for ensuring that the antenna device is properly positioned in a direction towards the tissue targeted for ablation. Furthermore, although only three angles have been shown, it should be noted that this is not a limitation and that other angles may be used.

Several embodiments associated with angled positioning and deployment of the antenna device will now be described in detail. It should be appreciated, however, that the present invention may be embodied in many other specific forms without departing from the spirit or scope of the invention, and may be practiced without some or all of these specific details.

In one embodiment, the ablation assembly may include a biasing member that is specifically formed and shaped for urging the antenna device to a predetermined

bent position. That is, the biasing member has a predetermined shape that corresponds to the angled position of the antenna device. As soon as the antenna device is advanced into the organ cavity the biasing member moves to assume its predetermined shape and thus the antenna device moves to the predetermined bent position. The biasing member generally consists of one or more pre-shaped elastic or spring like strips or rods that extend through the ablation arrangement in the area of the antenna device. The strips or rods may be arranged to have a circular, rectangular, or other cross section shape. By way of example, stainless steels, plastics and shape memory metals may be used.

In one implementation of this embodiment, the spring like material is a shape memory metal such as NiTi (Nitinol). Nitinol is a super elastic material that typically exhibits superb flexibility and unusually precise directional preference when bending. Accordingly, when the antenna device is positioned within the cavity of an organ, the nitinol strip enables the antenna device to conform to the inner wall of the organ. Similarly, when the antenna device is withdrawn from the organ, the Nitinol strip facilitates straightening to allow removal through the probe.

In another embodiment, the assembly may include a steering system for bending the antenna device to a predetermined bent position. The steering system generally includes one or more wires that extend through the ablation arrangement. The wires are used to pull the antenna device from an unbent position to a bent position causing controlled, predetermined bending at the antenna device. The pull wires are generally fastened to anchors, which are disposed (attached to) at the proximal end of the antenna device. In this type of arrangement, a steering element, located on the handle 50, may be used to pull on the wires to facilitate the bending. However, the actual position of the handle may vary according to the specific needs of each ablation assembly. Steering systems are well known in the art and for the sake of brevity will not be discussed in greater detail.

In another embodiment, the needle shaft of the probe can be pre-bent or curved to direct the antenna device to its advanced position. Referring to Fig. 5, the needle shaft 44 of the probe 12 includes a curved section 55 which redirects the

position of the antenna device 30 in a manner skewed from the axis 40 of the proximal end 14 of the probe 12. As the distal end of the antenna device 30 contacts the curved wall 55 of the insert passage, the antenna device 30 is urged toward the distal penetration opening 47 and into the cavity of organ 18 at an angle 38 relative to axis 40. Although the probe is shown as having a substantially right angle, it should be noted that the angle of the curved portion may vary according to the specific needs of each ablation assembly. For example, the angle 38 may also be configured to be acute or obtuse (such as in Fig. 4A & 4B) relative to the longitudinal axis 40.

Referring back to Figs. 2 & 3, the ablation tool 24 is illustrated having an elongated flexible transmission line 28 and an antenna device 30 coupled to the distal end of the transmission line 28. The transmission line 28 is adapted for insertion into the probe 12 and is arranged for actuating and/or powering the antenna device 30. In microwave devices, a coaxial transmission line is typically used, and therefore, the transmission line 28 includes an inner conductor 31, an outer conductor 32, and a dielectric material 33 disposed between the inner and outer conductors 31, 32. Furthermore, at the proximal end of the transmission line 28 is an electrical connector 42 adapted to electrically couple the transmission line 28, and therefore the antenna device 30, to the energy source (not shown). The transmission line 28 may also include a flexible outer tubing (not shown) to add rigidity and to provide protection to the outer conductor 32. By way of example, the flexible outer tubing may be made of any suitable material such as medical grade polyolefins, fluoropolymers, or polyvinylidene fluoride.

As shown in Figs. 2B-D, the antenna device 30, which is also adapted for insertion into the probe 12, generally includes an antenna wire 36 having a proximal end that is coupled directly or indirectly to the inner conductor 31 of the transmission line 28. A direct connection between the antenna wire 36 and the inner conductor 31 may be made in any suitable manner such as soldering, brazing, ultrasonic or laser welding or adhesive bonding. As will be described in more detail below, in some implementations, it may be desirable to indirectly couple the antenna to the inner conductor through a passive component in order to provide better impedance matching between the antenna device and the transmission line.

09660466 " 091200

In another embodiment, the antenna device 30 can be integrally formed from the transmission line 28 itself. This is typically more difficult from a manufacturing standpoint but has the advantage of forming a more rugged connection between the antenna device and the transmission line. This design is generally formed by removing the outer conductor 32 along a portion of the coaxial transmission line 28. This exposed portion of the dielectric material medium 33 and the inner conductor 31 embedded therein define the antenna device 30 which enables the electromagnetic field to be radiated substantially radially perpendicular to the inner conductor 31. In this type of antenna arrangement, the electrical impedance between the antenna device 30 and the transmission line 28 are substantially the same. As a result, the reflected power caused by the low impedance mismatch is also substantially small which optimizes the energy coupling between the antenna and the targeted tissues.

The antenna wire 36 is formed from a conductive material. By way of example, spring steel, beryllium copper, or silver plated copper may be used. Further, the diameter of the antenna wire 36 may vary to some extent based on the particular application of the ablation assembly and the type of material chosen. By way of example, in coronary applications using a monopole type antenna, wire diameters between about 0.005 inches to about 0.020 inches work well. In the illustrated embodiment, the diameter of the antenna is about 0.013 inches.

In an alternate embodiment, the antenna wire 36 can be formed from a shape memory metal such as NiTi (Nitinol). As mentioned, Nitinol is a super elastic material that typically exhibits superb flexibility and unusually precise directional preference when bending. Accordingly, when the antenna device 30 is positioned within the cavity of an organ, the antenna wire 36 enables the antenna device 30 to conform to the inner wall of the organ. Similarly, when the antenna device 30 is withdrawn from the organ, the antenna wire 36 facilitates straightening to allow removal through the probe 12. It should be noted, however, that the electrical conductivity of the Nitinol is not very good, and as a result, Nitinol can heat significantly when power (e.g., microwave) is applied. In one implementation, therefore, a layer of good conducting material is disposed over the Nitinol. For example, silver plating or deposition may be used. The thickness of the good

conducting material can vary between about 0.00008 to about 0.001 inches, depending on the conductivity of the selected material.

The length of the ablative energy generated by the ablation instrument will be roughly consistent with the length of the antenna device 30. As a consequence, ablation devices having specified ablation characteristics can be fabricated by building ablation devices with different length antennas. By way of example, in coronary applications, an antenna length between about 20 mm and about 50 mm and more particularly about 30 mm may be used. In some applications, the probe may be used to introduce a measuring tool that is arranged to measure the ablative lesion distance needed for a particular procedure. According to the measurements, the length of the antenna device can be selected. For instance, in some coronary applications, the tool may be used to measure the distance between the mitral valve and the pulmonary veins.

As shown, the antenna wire 36 is a monopole formed by a longitudinal wire that extends distally from the inner conductor 31. However, it should be appreciated that a wide variety of other antenna geometries may be used as well. By way of example, non-uniform cross-section monopole, helical coils, flat printed circuit antennas and the like also work well. Additionally, it should be understood that longitudinally extending antennas are not a requirement and that other shapes and configurations may be used. For example, the antenna may be configured to conform to the shape of the tissue to be ablated or to a shape of a predetermined ablative pattern for creating shaped lesions.

Furthermore, the antenna wire 36 is generally encapsulated by an antenna enclosure 37. The antenna enclosure 37 is typically used to obtain a smooth radiation pattern along the antenna device 30, and to remove the high electromagnetic field concentration present when an exposed part of the antenna wire is in direct contact with the tissue to be ablated. A high field concentration can create a high surface temperature on the tissue to ablate which is not desirable, especially for cardiac applications. The antenna enclosure 37 may be made of any suitable dielectric material with low water absorption and low dielectric loss tangent such as Teflon or polyethylene. As will be described in greater detail below, in some implementations,

it may be desirable to adjust the thickness of the antenna enclosure 37 in order to provide better impedance matching between the antenna device 30 and the tissue targeted for ablation. Although exposing the antenna wire is not typically done because of the high field concentration, it should be noted that the dielectric material forming the antenna enclosure 37 can be removed to form an exposed metallic antenna.

As shown in Fig. 3B, the outer conductor 32 is arranged to have a distal portion 39 that is exposed, beyond the penetration end 16 of the probe 12, when the antenna device 30 is in its advanced position. While not wishing to be bound by theory it is generally believed that the radiated field tends to be more confined along the antenna device 30 when the distal end of the outer conductor 32 is extended in the organ cavity and exposed to the surrounding medium. By way of example, an exposed outer conductor having a length of about 1 mm to about 2 mm works well. Although the outer conductor is shown and described as being exposed it should be understood that this is not a limitation and that the ablation arrangement can be made with or without an exposed outer conductor.

In one embodiment, the antenna device and the outer conductor are covered by a layer of dielectric. This layer of dielectric helps to remove the high concentration of electromagnetic field generated by the uncovered distal portion of the outer conductor. This configuration is better suited for cardiac applications because the high field concentration can potentially generate coagulum or carbonization that can trigger an embolic event. As shown in Figs. 6A & 6B, the ablation tool 24 includes a protective sheath 45 that surrounds the outer periphery of the antenna device 30 and a portion of the outer conductor 32 of the transmission line 28. More specifically, the protective sheath 45 is arranged to cover at least a portion of the exposed distal portion 39 of the outer conductor 32 and the antenna enclosure 37. As shown, the protective sheath may also cover the distal end of the antenna enclosure 37. By way of example, the protective sheath may be formed from any suitable dielectric material such as Teflon (PTFE), FEP, Silicon and the like.

In accordance with one embodiment of the present invention, the ablation arrangement is arranged to transmit electromagnetic energy in the microwave

inner conductor 31 and the outer conductor 32, as well as the size, shape and material of the dielectric material medium must be carefully selected. Each of these variables, together with other factors related to the antenna device, may be used to adjust the impedance and energy transmission characteristics of the antenna device. Such preferable dielectric materials include air expended TEFLONTM, while the inner and outer conductors are composed of silver or copper. The impedance of the transmission line may be determined by the equation:

$$Z_0 = \frac{60 \cdot \ln(b/a)}{\sqrt{\epsilon_r}}$$

where “b” is the diameter of the dielectric material medium, “a” is the diameter of the inner conductor and ϵ_r is the dielectric constant of the dielectric material medium 33. It will be understood that a characteristic impedance other than fifty ohms can also be used to design the microwave ablation system. Also, in order to obtain good mechanical characteristics of the coaxial cable assembly, it is important to consider the hardness or malleability of the selected material.

As it was explained earlier, it is also important to match the impedance of the antenna with the impedance of the transmission line. As is well known to those skilled in the art, if the impedance is not matched to the transmission line, the microwave power is reflected back to the generator and the overall radiation efficiency tends to be well below the optimal performance. Several embodiments associated with tuning (e.g., improving or increasing the radiation efficiency) the antenna device will now be described in detail.

In one embodiment, an impedance matching device is provided to facilitate impedance matching between the antenna device and the transmission line. The impedance matching device is generally disposed proximate the junction between the antenna and the transmission line. For the most part, the impedance matching device is configured to place the antenna structure in resonance to minimize the reflected power, and thus increase the radiation efficiency of the antenna structure. In one implementation, the impedance matching device is determined by using a Smith

Abacus Model. The impedance matching device may be determined by measuring the impedance of the antenna with a network analyzer, analyzing the measured value with a Smith Abacus Chart, and selecting the appropriate matching device. By way of example, the impedance matching device may be any combination of serial or parallel capacitor, resistor, inductor, stub tuner or stub transmission line. An example of the Smith Abacus Model is described in Reference: David K. Cheng, "Field and Wave Electromagnetics," second edition, Addison-Wesley Publishing, 1989, which is incorporated herein by reference.

In another embodiment, as shown in Fig. 7, the antenna device 30 includes a tuning stub 63 for improving the radiation efficiency of the antenna device 30. The tuning stub 63 is a circumferentially segmented section that extends distally from the distal end 53 of the outer conductor 32. In some embodiments, the tuning stub 63 is integrally formed from the outer conductor 32 and in other embodiments, the tuning stub 63 is coupled to the outer conductor 32. As shown, the tuning stub 63 is generally positioned on one side of the antenna device 30, and more particularly to the side which is closest to the tissue targeted for ablation (e.g., angular component side). The tuning stub 63 is also arranged to partially cover or surround the antenna enclosure 37. By way of example, the tuning stub 63 may cover between about 25 % to about 50 % of the perimeter of the antenna enclosure 37. Furthermore, the length L of the tuning stub 63 may be adjusted to further improve the radiation efficiency of the antenna device 30. For example, by increasing the length L, less power is reflected at the entrance of the antenna device 30 and the radiation efficiency of the system is increased. The radiation efficiency of the antenna device 30 is maximized when the resonance frequency is the same as the electromagnetic signal produced by the generator (2.45 GHz for example).

In another embodiment, as shown in Fig. 8, the antenna device 30 includes a pair of director rods 65 for improving the radiation efficiency of the antenna device 30. As shown, the director rods 65 are generally positioned on one side of the antenna device 30, and more particularly to the side which is closest to the tissue targeted for ablation (e.g., angular component side). The director rods 65 are disposed on the periphery of the antenna enclosure 37 and may be positioned anywhere along the length of the antenna device 30. By way of example, one of the director rods 65 may

be positioned proximate the distal end of the antenna device 30, while the other director rod 65 may be positioned proximate the proximal end of the antenna device 30. The position of the director rods may be adjusted to further improve the radiation efficiency of the antenna device 30. The director rods are generally formed from a suitable metallic material such as silver, and may also be formed from any material, which is silver-plated, for example, silver plated stainless steel or silver plated copper. Furthermore, the size (length and width) of the director rods 65 may be adjusted to further improve the radiation efficiency of the antenna device 30. It should be appreciated that a pair of rods is not a limitation and that a single rod or more than a pair rods may be used.

One particular advantage of using microwave energy is that the antenna device does not have to be in contact with targeted tissue in order to ablate the tissue. This concept is especially valid for cardiac ablation. For example, when a microwave antenna is located in the atrium, the radiated electromagnetic field does not see an impedance change between the blood and the myocardium (since the complex permittivity of these two media are similar). As a result, almost no reflection occurs at the blood-myocardium interface and a significant part of the energy will penetrate in the tissue to produce the ablation. In addition, the circulating blood between the antenna device and the tissue to be ablated helps to cool down the tissue surface. As such, the technique is potentially safer since it is less prone to create coagulation and/or carbonization. By way of example, a non-contact distance of about 1 to about 2 mm may be used. Furthermore, although not having contact provides certain advantages it should be noted that this is not a limitation and that the antenna device, and more particularly the antenna enclosure, may be positioned in direct contact with the tissue to ablate.

Furthermore, as is well known to those skilled in the art, it is more difficult to ablate tissues when the antenna device is surrounded by air. That is, there is a strong difference in the physical properties (the complex permittivity) between tissue and air. Therefore, in one embodiment, when the antenna device is not directly touching the tissue to be ablated, the surrounding cavity is filled with a liquid before ablating the tissue. As a result of filling the cavity with liquid, a better ablation may be achieved that is potentially safer since it is less prone to create coagulation and/or

carbonization. By way of example, liquids such as isotonic saline solution or distilled water may be used.

In some embodiments, as shown in Figs. 9A & 9B, the antenna device 30 is adapted to deliver electromagnetic energy (e.g., microwave) in directions extending substantially radially perpendicularly from the longitudinal axis 51 of the antenna wire 36 and through the antenna enclosure 37. That is, the antenna device 30 generally produces a radial isotropic radiation pattern 41 wherein the generated energy is homogeneously distributed around its volume. By way of example, the radiation pattern 41 generated by the antenna device 30 generally has an ellipsoidal shape along the length of the antenna device 30 (as shown in Fig. 9A), and a circular shape around its width (as shown in Fig. 9B).

It should be appreciated, however, that other ablative patterns may be needed to produce a particular lesion (e.g., deeper, shallower, symmetric, asymmetric, shaped, etc.). Accordingly, the antenna device may be arranged to provide other ablative patterns. For example, the antenna device may be arranged to form a cylindrical ablative pattern that is evenly distributed along the length of the antenna, an ablative pattern that is directed to one side of the antenna device, an ablative pattern that supplies greater or lesser energy at the distal end of the antenna device and/or the like. Several embodiments associated with adjusting the ablative pattern of the antenna device will now be described in detail.

In one embodiment, the thickness of the antenna enclosure is varied along the longitudinal length of the antenna device in order to adjust the radiation pattern of the electromagnetic field to produce a better temperature profile during ablation. That is, the antenna enclosure thickness can be used to improve field characteristics (e.g., shape) of the electromagnetic field. As a general rule, a thicker enclosure tends to cause a decrease in radiation efficiency, and conversely, a thinner enclosure tends to cause an increase in radiation efficiency. Thus, by varying the thickness along the length of the antenna, the amount of energy being delivered to the tissue can be altered. As such, the thickness can be varied to compensate for differences found in the tissue being ablated. In some cases, the antenna device can be configured to deliver a greater amount of energy to a specific area and in other cases the antenna

device can be configured to deliver energy more uniformly along the length of the antenna. For instance, if the delivered energy at the proximal end of the antenna is greater than the energy at the distal end, then the thickness of the dielectric material can be increased at the proximal end to reduce the radiation efficiency and therefore create a more uniform radiation pattern along the antenna. Consequently, a more uniform heating distribution can be produced in the tissue to ablate.

In an alternate implementation of this embodiment, as shown in Fig. 10, the antenna device 30 includes a tuning sleeve 77 for altering the radiation pattern of the antenna device 30. The tuning sleeve 77 is formed from a suitable dielectric material and is arranged to increase the thickness of the antenna enclosure 37. By way of example, the tuning sleeve may be formed from the same material used to form the antenna enclosure. In some embodiments, the tuning sleeve 77 is integrally formed from the antenna enclosure 37 and in other embodiments, the tuning sleeve 77 is coupled to the antenna enclosure 37. Furthermore, the tuning sleeve 77 is disposed around the periphery of the antenna enclosure 37 and may be positioned anywhere along the length of the antenna device 30. By way of example, the tuning sleeve may be positioned at the proximal end or distal end of the antenna device, as well as anywhere in between the proximal and distal ends of the antenna device. As should be appreciated, the position and length of the tuning sleeve 77 may also be adjusted to alter the radiation pattern of the antenna device. Although the tuning sleeve is shown as surrounding the antenna enclosure, it should be noted that it may also be circumferentially segmented. In addition, it should also be understood that a single sleeve is not a limitation and that a plurality of sleeves may be used.

In some embodiments, the tip of the antenna wire can be exposed to further alter the field characteristics. An exposed tip generally produces "tip firing", which can be used to produce more energy at the distal end of the antenna. In other embodiments, the stub tuner may be used to alter the radiation pattern of the antenna device. In other embodiments, the director rods may be used to alter the radiation pattern of the antenna device.

In another embodiment, as shown in Fig. 11, the antenna device 30 includes a reflector 71, which is arranged to direct a majority of an electromagnetic field to one

side of the antenna wire 36 and thus to one side of the antenna device 30. In this embodiment, the reflector 71 is positioned laterally to a first side of the antenna wire 36 and is configured to redirect a portion of the electromagnetic field that is transmitted towards the reflector 71 to a second side of the antenna wire 36 opposite the reflector 71. Correspondingly, a resultant electromagnetic field including a portion of the generated and a portion of the redirected electromagnetic field is directed in a desired direction away from the second side of the antenna wire 36. The desired direction is preferably in a direction towards the tissue to be ablated and thus the reflector is disposed on the side of the antenna device opposite the direction set for ablation. Furthermore, the reflector is disposed substantially parallel to the antenna to provide better control of the electromagnetic field during ablation.

The reflector is generally coupled to the outer conductor of the transmission line. Connecting the reflector to the outer conductor serves to better define the electromagnetic field generated during use. That is, the radiated field is better confined along the antenna, to one side, when the reflector is electrically connected to the outer conductor of the transmission line. The connection between the reflector and the outer conductor may be made in any suitable manner such as soldering, brazing, ultrasonic welding or adhesive bonding. In other embodiments, the reflector can be formed from the outer conductor of the transmission line itself. This is typically more difficult from a manufacturing standpoint but has the advantage of forming a more rugged connection between the reflector and the outer conductor. In other embodiments, metallization techniques are used to apply a reflective surface onto the antenna enclosure.

As can be appreciated, by those familiar with the art, by forming a concentrated and directional electromagnetic field, deeper penetration of biological tissues may be obtained during ablation and the biological tissue targeted for ablation may be ablated without heating as much of the surrounding tissues and/or blood. Further, since the radiated power is not lost in the blood, less power is generally required from the power source, and less power is generally lost in the transmission line. Additionally, this arrangement may be used to form linear lesions that are more precise.

Furthermore, the reflector 71 is typically composed of a conductive, metallic mesh or foil. One particularly suitable material is silver plated copper. Another suitable arrangement may be a stainless steel mesh or foil that has a layer of silver formed on its inner peripheral surface. However, it should be understood that these materials are not a limitation. Furthermore, the actual thickness of the reflector may vary according to the specific material chosen.

The reflector 71 is configured to have an arcuate or meniscus shape (e.g., crescent), with an arc angle that opens towards the antenna wire 36. Flaring the reflector 71 towards the antenna wire 36 serves to better define the electromagnetic field generated during use. The arc angle is typically configured between about 90° to about 180°. By way of example, an arc angle of about 120° works well. Additionally, it has been found that if the arc angle 90 is greater than 180° the radiation efficiency of the antenna arrangement decreases significantly.

Turning now to Figs. 12A & 12B, an alternative embodiment to the present invention is illustrated wherein a metallic needle shaft 44 is used as an electrical continuation of the outer conductor 32. In this embodiment, the outer conductor 32 includes a contact member 60 that is disposed at the distal end of the outer conductor 32. The contact member 60 is arranged to electrically couple the outer conductor 32 to the needle shaft 44 when the ablation tool is moved through the probe 12, and more particularly when the ablation tool reaches its deployed position (as shown in Fig. 12B). Furthermore, the distal portions of the transmission line 28 are appropriately sized such that only the dielectric material medium 33 and the inner conductor 31 are slideably received in the lumen 22 of the metallic needle shaft 44. That is, a distal portion of the outer conductor 32 has been removed so that the outer conductor 32 is not carried by the lumen 22 of the needle shaft 44. As such, the contact member 60 is adapted to contact the distal end 46 of the needle shaft 44. By providing an electrical connection, the metallic needle shaft 44 can act as an extension of the outer conductor 32 of the transmission line 28.

For ease of discussion, portions of the ablation tool 24 that are disposed proximally from the contact member 60 are designated with an A, and portions of the

ablation tool 24 that are disposed distally from the contact member 60 are designated with a B. Accordingly, the assembly comprising the inner conductor 31B, the dielectric material 33B and the metallic needle shaft 44 creates a distal coaxial cable 28B. That is, the needle shaft 44 conductively functions as a shield for the transmission line 28 from the access opening 46 to the distal penetration opening 47 of the probe 12. As best viewed in Fig. 12B, this shielding effect commences when the outer conductor 32 of the transmission line 28 and the needle shaft 44 of the probe 12 are in conductive communication with one another. The outer conductor 32 must therefore be in conductive communication with the metallic needle shaft 44 at least when the antenna device 30 is radiating electromagnetic energy.

As shown in Fig 12B, the contact member 60 is adapted to electrically contact the proximal part 46 of the needle shaft 44 when the antenna device 30 is fully extended through the needle shaft 44 and into the targeted organ 18. Thus, the contact member 60 not only operates as an electrical connector between the outer conductor 32 and the needle shaft 44 but also as a stop device that limits the amount of penetration into the organ. In most configurations, the size of the contact member 60 is merely larger than that of the access opening.

As it was explained earlier, it is also important to match the impedance of the antenna with the impedance of the transmission line. As is well known to those skilled in the art, if the impedance is not matched to the transmission line, the microwave power is reflected back to the generator and the overall radiation efficiency tends to be well below the optimal performance. Accordingly, the dimensions of the distal coaxial cable elements are generally selected to match the impedance of the proximal transmission line. As should be appreciated, the cross sectional dimensions of 28B, 31B and 33B may be different from 28A, 31A and 33A.

With regards to the length of the antenna device 30, in the configuration of Figs. 12A&B, the length is generally defined from the center of the distal penetration opening 47 to the distal end of the antenna wire 36. Several important factors that will influence the antenna length include the desired length of the ablation, the antenna configuration, the frequency of the electromagnetic wave and the impedance

match of the antenna within the tissue or the organ cavity. The matching of the antenna is performed by adjusting its length so that the radiation efficiency is adequate when the antenna is used in the tissue or in the organ cavity. As an example, the radiation efficiency is generally adequate when the return loss of the antenna is in the range of -10 dB to -13 dB at 2.45 GHz. Instruments having specified ablation characteristics can be designed by varying the antenna length. For example, in microwave coronary applications for treating atrial fibrillation, the antenna device may have an antenna wire diameter of about 0.013 inch, a dielectric material medium diameter of about 0.050 inch and a length in the range of approximately 20 mm to 30 mm.

The distal coaxial cable can also be used as a serial stub tuner to match the impedance of the antenna device 30 and the transmission line 28. This arrangement is advantageous since, while maintaining the electrical continuation and the impedance match between the generator and the antenna, the diameters of the inner conductor 31 and the dielectric material medium 33 can be maximized relative the insert passage 22. The larger diameters, consequently, facilitate axial penetration into the organ due to the increased lateral and axial rigidity without compromising the impedance matching of about fifty (50) ohms.

Turning now to Figs. 13A & 13B, an alternative embodiment to the present invention is illustrated wherein the ablation assembly 10 includes a clamping portion 79 for positioning the antenna device 30 proximate the wall 82 of the organ 18. The clamping portion 79 and the antenna device 30 are arranged to facilitate linear positioning of the antenna device 30. The clamping portion 79 generally includes a clamping finger 81 and a bar slide 84 that is slidably coupled to the needle shaft 44 and is configured to move relative to the probe 12. In general, the bar slide 84 is configured to slide within at least one guide track 86 that is structurally attached to the needle shaft 44. The clamping portion 79 is also arranged to be substantially aligned (in the same plane) with the antenna device 30 when the antenna device 30 is in its angular position.

Accordingly, when the antenna device 30 is properly positioned, the clamping portion 79 is moved in a direction towards the organ 18 to pinch the organ wall

between the antenna 30 and the clamping finger 81. That is, the clamping finger 81 is moved to a position that contacts the outer wall 88 of the organ 18, wherein after contact and upon further finger movement the antenna device 30 is forced to move in a direction towards the probe 12. As a result, the antenna device 30 and clamping finger 81 exert opposite forces on opposite sides of the organ wall. By way of example, the finger and the antenna device can be used to sandwich the myocardium of the heart wherein the finger is applying a force to the epicardial surface and the antenna device is applying an opposing force to the endocardium. This particular approach tends to create a more uniform ablating surface, which as result, produces a better linear lesion.

The clamping finger is generally configured to be parallel to the angular position of the deployed antenna device. By way of example, if the antenna device is configured to have an angle of about 60 degrees relative to the axis of the probe, then the finger may be configured to have an angle of about 60 degrees relative to the axis of the probe. In this manner, the antenna device and clamping finger can pinch the organ wall evenly. Alternatively, the clamping finger can be shaped to conform to the shape of the outer wall. Further still, the clamping finger generally has a length that is substantially equivalent to the length of the antenna device. However, it should be noted that the length may vary according to the specific design of each ablation assembly. Additionally, the slide bar may be connected to a handle for physically actuating the linear movement, a knob or jack for mechanically actuating the linear movement, or an air supply for powering the linear movement. A locking mechanism may also be used to lock the engagement between the clamp finger and the antenna device so that the antenna device does not move from the target area during ablation.

Moreover, a seal may be used between the clamp finger and the outer wall of the organ to seal the puncture site. Additionally, a suction device may be disposed on the clamping finger to anchor and temporarily position the clamping finger to the outer organ wall. Alternatively, a balloon that is attached to the probe may be used to pinch the organ wall between the inflated balloon and the angularly positioned antenna device.

Turning now to Figs. 14A & 14B, an alternative embodiment to the present invention is illustrated wherein the ablation assembly 10 includes a ground plane 89 for coupling electromagnetic energy 90 through the organ wall 35. The ground plane 89 generally provides a metallic surface that attracts the electric field generated by the antenna device 30 and therefore a more intense electromagnetic field 90 is produced between the antenna device 30 and the ground plane 89. Accordingly, the electromagnetic field 90 emitted by the antenna device 30 is more constrained in the tissue 35 between the antenna device 30 and the ground plane 89, which as a result helps to create the ablation.

As will be appreciated by those familiar with the art, inserting the tissue to ablate between the ground plane 89 and the antenna 30 has several potential advantages over conventional antenna structures. For example, by forming a concentrated electromagnetic field, deeper penetration of biological tissues may be obtained during ablation and the biological tissue targeted for ablation may be ablated without heating as much of the surrounding tissues and/or blood. Further, since the radiated power is not lost in the blood, less power is generally required from the power source, and less power is generally lost in the transmission line, which tend to decrease its temperature. Additionally, this arrangement may be used to form lesions that are more precise.

In this embodiment, the ground plane 89 is electrically coupled to the outer conductor 32 of the transmission line 28. The ground plane 89 is generally disposed on the needle shaft 44 of the probe 12 at a predetermined distance Q away from the deployed antenna device 30 (as shown in Fig. 14B). The predetermined distance Q is arranged to place the ground plane 89 in close proximity to the antenna device 30, and outside the outer wall of the organ 18 when the needle shaft 44 is position inside the organ wall 35. By way of example, in coronary applications, a distance between about 1 mm and about 15 mm may be used.

Moreover, the ground plane 89 is generally configured to be parallel to the angular position of the antenna device 30. By way of example, if the antenna device 30 is configured to have an angle of about 60 degrees relative to the axis of the probe, then the ground plane may be configured to have an angle of about 60 degrees relative

to the axis of the transmission line. In this manner, the antenna and the ground plane can couple energy more evenly. Alternatively, the ground plane can be shaped to conform to the shape of the outer wall. Further still, the ground plane generally has a length that is substantially equivalent to the length of the antenna device 30. By way of example, a ground plane length between about 20 mm and about 50 mm works well. It should be noted, however, that the length may vary according to the specific needs of each ablation assembly. The ground plane is also arranged to be substantially aligned (in the same plane) with the angular component of the antenna device 30.

The ground plane 89 may be formed from a wire, strip or rod, and may be arranged to have a circular, rectangular, or other cross section shape. Furthermore, the ground plane 89 is formed from a suitable conductive material such as stainless steel or silver. The dimensions of the ground plane 89 may vary to some extent based on the particular application of the ablation assembly and the type of material chosen. Additionally, the ground plane may be printed on or enclosed inside of a flexible dielectric substrate (such as Teflon or polyimide). Furthermore, the connection between the ground plane 89 and the outer conductor 32 may be made in any suitable manner such as soldering, brazing, ultrasonic welding or adhesive bonding.

The ground plane 89 can be configured in a variety of ways. In some embodiments, the ground plane may be rigidly or structurally coupled to the needle shaft of the probe. In other embodiments, the ground plane may be pivoted or slidably coupled to the needle shaft of the probe. For example, the clamping finger, as described above in Fig. 13, can be arranged to be a ground plane for the antenna. In other embodiments, the ground plane may be flexible in order to follow the natural curvature of the organ. In other embodiments, the ground plane may be biased to contact the tissue. Further still, in some embodiments, the ground plane may be configured to act as a stop device that limits the amount of probe penetration into the organ.

In an alternate embodiment, the ground plane may be properly positioned across from the antenna device with a ground plane positioner. The ground plane positioner generally includes tubular member having passage therein. In this embodiment, the ground plane is advanced longitudinally through the passage of the

tubular member to the distal opening of the passage. Upon subsequent advancement, the ground plane may be manipulated to extend through distal opening of the passage and to the outer wall of the organ. Such advancement preferably allows the ground plane to assume a predetermined position that is substantially aligned with the deployed antenna device such that the organ wall is disposed between the ground plane and the antenna device. In one embodiment, the assembly may include a biasing member that is specifically formed and shaped for urging the ground plane to a predetermined bent position. In another embodiment, the assembly may include a steering system for bending the ground plane to a predetermined bent position. In another embodiment, the needle shaft of the tubular member can be prebent or curved to direct the ground plane to its advanced position.

Referring to Fig. 15, the ablation assembly 10 includes a positioner 91 having a tubular member 92 and a passage 94 therein. As mentioned above, the ground plane 96 is electrically coupled to the outer conductor 32 of the transmission line 28. In this particular embodiment, the tubular member includes a curved section 95 which redirects the position of the ground plane 96 in a manner skewed from the axis 40 of the proximal end 14 of the probe 12. As the distal end of the ground plane 96 contacts the curved wall 95 of the passage 94, the ground plane 96 is urged out of the distal opening 97 and to an outer wall position that is substantially aligned with the angled antenna device 30. Additionally, the ground plane 96 may be fixed to the transmission line 28 such that when the antenna device 30 is deployed so is the ground plane 96.

Turning now to Fig. 16, an alternative embodiment to the present invention is illustrated wherein the ablation assembly 10 is inserted through an access device 70, which is positioned in the body cavity 20. The access device 70 is generally disposed inside a small incision that is made in the body cavity 20. The access device includes a passage 72 that is appropriately sized for receiving the ablation assembly 10 such that the needle shaft 44 of probe 12 can be introduced into the body cavity 20. As can be appreciated, the passage 72 allows access to the targeted organ 18. Access devices are well known to those skilled in the art and therefore they will not be described in detail herein.

Referring now to Fig. 17, the described ablation assembly 10 is used for ablating cardiac tissues, in accordance with one embodiment of the present invention. The ablation assembly 10 is especially beneficial in navigating around certain regions of the heart 200. For example, the ablation assembly 10 may be used to bypass the layers of fat 202 or veins 204 that surround the epicardial surface 206 (e.g., outer wall) of the heart 200. By way of example, the vein 204 may be the coronary sinus, which is located just superior to the junction between the left atrium 240 and the left ventricle 246. As mentioned, fat 202 is a good microwave absorber and a very poor thermal conductor. Furthermore, veins 204 readily transfer heat through blood flow. As a result, fat 202 and veins 204 are very difficult to ablate through from the epicardial surface (not enough thermal energy to ablate). Accordingly, by positioning the antenna device 30 inside a cavity 208 of the heart 200 (e.g., through the layer of fat), the ablative energy can be supplied to the endocardium 210 rather than the obstructed epicardial surface 206 thereby effectively ablating the targeted tissue. By way of example, the cavity 208 may be the left atrium 240, the right atrium 242, the left ventricle 246 or the right ventricle 244.

The ablation assembly 10 may be used to treat a variety of heart conditions. In one embodiment, the ablation assembly is used to treat atrial fibrillation and in another embodiment the ablation assembly is used to treat atrial flutter. Several implementations associated with ablating cardiac tissues using the ablation assembly 10 will now be described.

In one implementation, the ablation assembly 10 is used to create lesions between any of the pulmonary veins 212 of the heart 200 in order to treat atrial fibrillation. In another implementation, the ablation assembly 10 is used to create lesions from one of the pulmonary veins 212 to the mitral valve 213 of the heart 200 in order to avoid macro-reentry circuit around the pulmonary veins in a lesion pattern used to treat atrial fibrillation. In another implementation, the ablation assembly 10 is used to create lesions from one of the pulmonary veins 212 to the left atrial appendage of the heart 200 also to avoid macro-reentry circuit around the pulmonary veins in a lesion pattern used to treat atrial fibrillation.

In one implementation, the ablation assembly 10 is used to create lesions between the inferior caval vein 216 to the tricuspid valve 214 of the heart 200, in order to treat typical or atypical atrial flutter. In another implementation, the ablation assembly 10 is used to create lesions along the cristae terminalis in the right atrium 242 of the heart 200 in order to treat typical or atypical atrial flutter. In another implementation, the ablation assembly 10 is used to create lesions from the cristae terminalis to the fossae ovalis in the right atrium 242 of the heart 200 in order to treat typical or atypical atrial flutter. In yet another implementation, the ablation assembly 10 is used to create lesions on the lateral wall of the right atrium 242 from the superior 220 to the inferior vena cava 216 in order to treat atypical atrial flutter and/or atrial fibrillation.

Although a wide variety of cardiac procedures have been described, it should be understood that these particular procedures are not a limitation and that the present invention may be applied in other areas of the heart as well.

A method for using the described microwave ablation assembly in treating the heart will now be described with reference to Fig. 17. Although only a heart is shown and described, it should be understood that other organs, as well as organ ducts, may be treated with ablation assembly. The method includes providing an ablation assembly such as any one of the ablation assemblies described herein. More particularly, the method includes providing a surgical device 10 having a probe 12 and an elongated microwave ablation arrangement 24. The probe 12 includes a passage extending therethrough from a proximal end 14 to an opposite distal end 16 thereof. The distal end 16 is adapted to penetrate through a muscular wall 222 (e.g., myocardium) of the heart 200. Furthermore, the elongated microwave ablation arrangement 24 includes a distal antenna 30 coupled to a transmission line, which in turn is coupled to a microwave energy source at a proximal end thereof. In accordance with the present invention, the method includes introducing the surgical device 10 into a body cavity 230. This may be by penetration of the body 232 or through an access device 70. Several surgical approaches are possible. For example, the surgical device may be introduced through an open chest, a posterior thoracotomy, a lateral thoracotomy (as shown in Fig. 10), or a sternotomy. The surgical procedure can also use an endoscope in order to visualize the ablation device during the

placement. These procedures are generally well known to those skilled in the art and for the sake of brevity will not be discussed in detail.

The method further includes penetrating the muscular wall 222 of the heart 200 with the distal end 16 of the elongated probe 12 and introducing the elongated probe 12 through the muscular wall 222 of the heart 200 and into an interior chamber 208 thereof. By way of example, the surgical tool 10 can be introduced into the left atrium 240, the right atrium 242, the right ventricle 244 or the left ventricle 246. Furthermore, before penetration a purse string suture may be placed in the heart wall proximate the area targeted for penetration so as to provide tension during penetration. Purse string sutures are well known in the art and for the sake of brevity will not be discussed in more detail.

The method also includes introducing the elongated microwave ablation device 24 into the passage of the elongated probe 12 and advancing the antenna 30 past the distal end 16 of the probe 12 such that the antenna 30 is disposed inside the interior chamber 208 of the heart 200. Upon advancement, the antenna 30 preferably assumes a predetermined position that substantially matches the shape and/or angular position of the wall to be ablated. By way of example, the position may place the antenna substantially parallel to the interior surface 210 (e.g. endocardium) of the penetrated muscular wall 222 and proximate the targeted tissue. Angled advancement may be accomplished in a variety of ways, for example, with a biasing member, a steering wire or a curved probe. Furthermore, the method includes generating a microwave field at the antenna that is sufficiently strong to cause tissue ablation within the generated microwave field.

In accordance with another aspect of the present invention, the ablation assembly includes a needle and a transmission line having a longitudinal axis. The needle is adapted to be inserted into a body cavity and to penetrate an organ (or duct) within the body cavity. The needle is also configured for insertion into a cavity within the organ and includes an antenna for transmitting electromagnetic energy. The transmission line is coupled to the antenna and configured for delivering electromagnetic energy to the antenna. Furthermore, the ablation assembly is arranged so that when the needle is finally inserted into the organ cavity, the antenna lies at an

angle relative to the longitudinal axis of the transmission line. In most cases, the needle or the transmission line is pre-shaped or bent at a predetermined position that is arranged to substantially match the shape and/or angular position of the wall to be ablated. In other cases, a biasing member or steering system, in a manner similar to biasing member and steering system described above, may be used to provide angled positioning.

Turning now to Figs 18-21, an ablation assembly, generally designated 100, is provided including a relatively thin needle 102 configured for emitting electromagnetic energy and having a penetration end 104 adapted to penetrate an organ 106. The needle 102 is axially rigid to allow for tissue penetration and may be longitudinally flexible to avoid damaging the organ 106 during positioning. The ablation assembly 100 further includes a transmission line 108 having a longitudinal axis 110 and a distal end 112 that is coupled to the proximal end 114 of the needle 102 for generating an electromagnetic field sufficiently strong to cause tissue ablation. At the proximal end 118 of the transmission line 110 is an electrical connector 120 adapted to electrically couple the antenna to an electromagnetic energy source (not shown). As shown, the needle 102 is bent at an angle 116 relative to the longitudinal axis 110 of the transmission line 108. In most embodiments, the bend is arranged to easily position the antenna parallel to the tissue to ablate by taking into consideration the angle of approach (the angle used to insert the needle through the organ).

Accordingly, the ablation assembly 100 utilizes the needle 102 to provide ablative energy within a cavity of the organ 106. That is, the distal penetration end 104 is used to pierce through an outer wall 122 of the organ 106 to position the needle 102 proximate and substantially parallel to an inner wall 124 of the organ 106. Once the needle 102 is positioned, ablative energy that is sufficiently strong to cause tissue ablation is emitted from the needle 102 to ablate a portion of the inner wall 124. This arrangement is especially beneficial when the areas targeted for ablation have obstructions along the outer wall of the organ. For example, the needle may be used to bypass and navigate around layers of fat or veins that surround the epicardial surface (e.g., outer wall) of the heart. Furthermore, the angled position of the needle assures that the ablative energy will be accurately transmitted in the targeted ablation region.

Referring to Fig. 21, the needle 102 includes an elongated antenna 130 and an antenna enclosure 132 that are adapted to pierce through organ 106 at a distal penetration end 104. By way of example, the distal penetration end 104 is in the form of a conventional beveled tipped needle or a beveled point chamfered needle which forms sharp cutting edge. As shown, the antenna 130 is encapsulated by the antenna enclosure 132, which is generally better suited to remove the high electromagnetic field concentration that is normally obtained when the metallic part of the antenna is in direct contact with the tissue. A high field concentration can create a high surface temperature on the tissue to ablate which is not desirable, especially for cardiac applications. The antenna enclosure 132 may be made of any suitable dielectric material (e.g., low loss tangent) with low water absorption such as medical grade epoxy, polyethylene or Teflon type products (e.g., bio compatible). As was described in great detail above, it may be desirable to adjust the thickness of the antenna enclosure in order to provide better impedance matching between the antenna and the tissue targeted for ablation. It is contemplated, however, that needle antenna enclosures having a thickness between about 0.002 inches and about 0.015 inches, and more particularly about 0.005 inches work well.

It should also be noted that the antenna enclosure may not be required for all ablation assemblies. By way of example, Figs. 22 & 24 show the ablation assembly 100 with an exposed antenna 130 having no antenna enclosure. However, it should be noted that in most situations the antenna enclosure is configured to insulate the antenna to avoid the charring and tissue destruction effects that are commonly experienced when the ablative elements, and more particularly, the metallic parts of the antenna, are directly in contact with the body's tissue or fluid.

The antenna 130 is formed from a conductive material. By way of example, spring steel, beryllium copper, or silver plated copper work well. Further, the diameter of the antenna 130 may vary to some extent based on the particular application of the ablation assembly and the type of material chosen. By way of example, in systems using a monopole type antenna, wire diameters between about 0.005 inch to about 0.020 inches work well. In the illustrated embodiment, the diameter of the antenna is about 0.013 inches.

As mentioned, the field generated by the antenna will be roughly consistent with the length of the antenna. That is, the length of the electromagnetic field is generally constrained to the longitudinal length of the antenna. Therefore, the length of the field may be adjusted by adjusting the length of the antenna. Accordingly, ablation arrangements having specified ablation characteristics can be fabricated by building ablation arrangements with different length antennas. By way of example, antennas having a length between about 20 mm and about 50 mm, and more particularly about 30 mm work well. Furthermore, the antenna shown is a simple longitudinally extending exposed wire that extends distally from the inner conductor. However it should be appreciated that a wide variety of other antenna geometries may be used as well. By way of example, helical coils, flat printed circuit antennas and other antenna geometries will also work well. Additionally, it should be understood that longitudinally extending antennas are not a requirement and that other shapes and configurations may be used. For example, the antenna may be configured to conform to the shape of the tissue to be ablated or to a shape of a predetermined ablative pattern for creating shaped lesions.

Referring back to Fig. 21, the transmission line 108 generally includes an inner conductor 134 and an outer conductor 136 separated by a dielectric material medium 138. An insulating sheath 140 is typically disposed around the outer conductor 136. Furthermore, the outer conductor 136 is generally arranged to have a portion 136A that extends from the distal end of the insulating sheath 140 so that it can be exposed. As mentioned, when the outer conductor 136 is exposed, the generated electromagnetic field is more constrained to the antenna and therefore the radiation efficiency tends to be greater. By way of example, an exposed outer conductor having a length of about 1 mm to about 2 mm works well. Although the outer conductor is shown and described as being exposed it should be understood that this is not a limitation and that the ablation arrangement can be made with or without an exposed outer conductor.

Furthermore, the transmission line 108 is provided by a conventional fifty (50) ohm coaxial design suitable for the transmission of microwave energy at frequencies in the range of about 400 to about 6000 megahertz. In the preferred embodiment, the

inner conductor 134 is provided by a solid metallic material core surrounded by a flexible semi-rigid dielectric material medium 138. The outer conductor 136 includes a braided sleeve of metallic wires surrounding the inner conductor 134 to provide shielding and good flexibility thereof. Furthermore, the insulating sheath is generally flexible and may be made of any suitable material such as medical grade polyolefins, fluoropolymers, or polyvinylidene fluoride. By way of example, PEBAX resins from Autochem of Germany have been used with success.

In most embodiments, the proximal end 114 of the antenna 130 is coupled directly or indirectly to the distal end 112 of the inner conductor 134 of the transmission line 108. A direct connection between the antenna 130 and the inner conductor 134 may be made in any suitable manner such as soldering, brazing, ultrasonic welding or adhesive bonding. As was described in great detail above, it may be desirable to indirectly couple the antenna to the inner conductor through a passive component in order to provide better impedance matching between the antenna device and the transmission line. In other embodiments, the antenna 130 can be integrally formed from the transmission line 108 itself. This is typically more difficult from a manufacturing standpoint but has the advantage of forming a more rugged connection between the antenna and the transmission line.

The ablation assembly 100 is preferably thin having a diameter in the range of between about 1.5 mm to about 3 mm, and more preferably about 2 mm. This relatively small diameter size is particularly suitable for use in most bodily organs, such as the heart, so as to minimize the puncture diameter and, thus, potential bleeding. It will be appreciated, however, that the present invention may be used to ablate other organs or tissue as well. Additionally, the ablation assembly must be sufficiently flexible to accommodate normal operational use, yet be sufficiently rigid to prevent buckling of the line during penetrative manipulation of the needle into the targeted organ.

In one embodiment, the ablation assembly 100 includes a bend 150 that places the needle 102 at an angle relative to the longitudinal axis 108 of the transmission line 110. As shown in Fig. 21, the bend 150 is placed along a distal portion of the transmission line. Alternatively, the bend 150 may be placed along a proximal

portion of the needle as shown in Fig. 23. In either case, the bend 150 is arranged such that when the needle 102 is introduced into the organ cavity, the needle is disposed at a predetermined position that is arranged to substantially match the shape and/or angular position of the wall to be ablated. That is, the needle is bent in a direction towards the tissue targeted for ablation. By way of example, the needle may be configured to be bent in a direction that places the needle substantially parallel and proximate the tissue to be ablated. Furthermore, bend 150 is arranged to be sufficiently rigid to prevent buckling of the line during penetrative manipulation of the needle into the targeted organ.

In Fig. 19, the ablation assembly 100 is shown perpendicularly penetrating the organ wall 106. It is contemplated, however, that this position is not always possible because some organs are particularly difficult to access, and therefore the needle may be inserted into the wall of the organ at different angles. Accordingly, the present invention may be configured to provide a range of angled bends. By way of example, an antenna position having an angle in the range of between about 45 degrees to about 135 degrees with respect to the longitudinal axis of the transmission line works well. However, it should be noted that this is not a limitation and that other angles, as well as other bend configurations, may be used. By way of example, the ablation assembly can be configured to have multiple bends, curvilinear bends, rectilinear bends, three dimensional bends or have a shape that conforms to the shape of the tissue to be ablated or the ablating line desired.

For ease of discussion, Figs. 25A & 25B show a variety of ablation assembly configurations. Fig. 25A shows the needle 102 in an acute angular position relative to longitudinal axis 110. Fig. 25B shows the needle 102 in an obtuse angular position relative to longitudinal axis 110. Again, these angular positions are important parameters for ensuring that the antenna device is properly positioned in a direction towards the tissue targeted for ablation.

Turning now to Fig. 26, an alternative embodiment to the present invention is illustrated wherein the ablation assembly 100 includes a handle 160 that provides gripping surfaces for manipulating the needle 102 through the organ wall. The handle 160 is configured for receiving surgical tools such as forceps (not shown). In

this manner, the needle 102 may be positioned in the organ by holding the handle 160 with forceps and maneuvering the forceps such that the needle 102 penetrates through the organ wall. Subsequently, the forceps may be used to position the needle 102 proximate the tissue targeted for ablation. The handle 160 is disposed on the transmission line 108 at a predetermined distance X away from the bent portion 150 of the assembly 100. The predetermined distance X is arranged to place the handle 160 in close proximity to the needle 102, and outside the outer wall of the organ when the needle 102 is positioned inside the organ. By way of example, in coronary applications, a distance between about 1 cm and about 3 cm works well. Furthermore, a handle formed from a polymer having a width between about 5 mm and about 10 mm, a length between about 2 mm and about 5 mm, and a height between about 5 mm and about 10 mm works well. Although the handle is shown as being rectangular it should be noted that this is not a limitation and that the handle can be arranged with a plurality of different shapes.

In one implementation, the handle is arranged to provide additional support (rigidity and strength) at the junction between the antenna and the inner conductor of the transmission line. In another implementation, the handle is arranged to enclose an impedance matching device located between the antenna and the inner conductor. Furthermore, in a manner analogous to the clamping portion (Fig. 13) described above, the handle can be arranged to be slidably coupled to the transmission line such that the handle can be used to clamp the wall of the organ between the bent needle and the handle. Additionally, a seal may be used between the handle and the outer wall of the organ to seal the puncture site. In another implementation, the handle may include a balloon for biasing contact between the handle and the bent antenna.

Turning now to Figs. 27A-27C, an alternative embodiment to the present invention is illustrated wherein the ablation assembly 100 includes a ground plane strip 170 for coupling electromagnetic energy through the organ wall 106. The ground plane 170 generally provides a metallic surface that attracts the electric field generated by the antenna 130 and therefore a more intense electromagnetic field 180 is produced between the antenna 130 and the ground plane 170. As a result, a more efficient, controlled and concentrated electric field can be used to ablate the targeted

tissue. Additionally, less power may be required from the power source because of the more efficient use of the energy.

In this embodiment, the ground plane 170 is electrically coupled to the outer conductor 136 of the transmission line 108. The ground plane 170 is generally disposed on the transmission line 108 at a predetermined distance Y away from the antenna 130 of the needle 102. The predetermined distance Y is arranged to place the ground plane in close proximity to the needle 102, and outside the outer wall of the organ 106 when the needle 102 is positioned inside the organ 106. By way of example, in coronary applications, a distance between about 1 mm and about 15 mm works well.

Additionally, the ground plane 170 must be sufficiently flexible to accommodate needle maneuvering, normal operational use and storage thereof, yet be sufficiently rigid to prevent buckling or bends in the ground plane when the needle is positioned inside the organ cavity. The ground plane 170 may be formed from a metallic foil. By way of example, silver, stainless steel or gold work well. The ground plane 170 can also be formed from a flexible dielectric substrate with one or two metallic surface(s). By way of example, KaptonTM or TeflonTM substrates work well. Further, the thickness of the ground plane 170 may vary to some extent based on the particular application of the ablation assembly and the type of material chosen. By way of example, a strip thickness between about 0.005 inch to about 0.040 inch works well. In the illustrated embodiment, the thickness of the ground plane strip is about 0.010 inch. Furthermore, the connection between the ground plane 170 and the outer conductor 136 may be made in any suitable manner such as soldering, brazing, ultrasonic welding or adhesive bonding.

Although the ground plane is shown and described as a strip it should be noted that this is not a limitation and that the ground plane may vary in form according to the specific needs of each assembly. By way of example, a metallic wire formed from silver having a diameter between about 1 mm and about 2 mm works well. Additionally, a plate formed from silver having a thickness between about 0.005 inch and about 0.040 inch and a width between about 2 mm and about 5 mm works well.

Moreover, the ground plane is generally configured to be parallel to the angular position of the needle 102. By way of example, if the needle is configured to have an angle of about 60 degrees relative to the axis of the transmission line, then the ground plane may be configured to have an angle of about 60 degrees relative to the axis of the transmission line. In this manner, the antenna and the ground plane can couple energy more evenly. Alternatively, the ground plane can be shaped to conform to the shape of the outer wall. Further still, the ground plane generally has a length that is substantially equivalent to the length of the antenna 130. By way of example, a ground plane length between about 20 mm and about 50 mm works well. It should be noted, however, that the length may vary according to the specific needs of each ablation assembly. The ground plane is also arranged to be substantially aligned (in the same plane) with the bent portion of the needle 102.

Alternatively, in one implementation, the ground plane is arranged to be part of the handle. In another implementation, the electrode is movably coupled to transmission line. For example, the ground plane may be pivotly or slidably coupled to the transmission line. In another implementation, the ground plane is biased to contact the tissue.

A method for using the described needle ablation assembly in treating an organ will now be described. The method includes providing a surgical device 100 having a needle 102 coupled to a transmission line 108. The transmission line 108 is arranged to have a portion with a longitudinal axis 110 and a proximal end 120 coupled to an electromagnetic energy source. By way of example, a microwave energy source that generates energy in the microwave frequency range works well. Furthermore, the needle 102 includes a distal end 104 that is adapted to penetrate through a wall of an organ 106 and an antenna 130 for generating a microwave field. By way of example, the organ may be a human heart and the wall may be the myocardium of the heart. The antenna 130 is also arranged to be in an angular position relative to the longitudinal axis 110 of the transmission line 108. By way of example, the needle or the transmission line may be pre-shaped or bent at a predetermined angular position.

In accordance with the present invention, the method includes introducing the surgical device 100 into a body cavity. This may be by penetration of the body or through an access device inserted in the body. By way of example, in most coronary applications, the introducing may be provided through the thorax region of the body or through an opened chest. The method further includes penetrating a wall of the organ 106 with the distal end 104 of the needle 102 and introducing the needle 102 through the wall of the organ 106 and into an interior chamber thereof. By way of example, the surgical tool 100 can be introduced into the left atrium, the right atrium, the right ventricle, or the left ventricle of the heart. Furthermore, before penetration a purse string suture may be placed in the heart wall proximate the area targeted for penetration so as to provide tension during penetration. Purse string sutures are well known in the art and for the sake of brevity will not be discussed in more detail.

The method also includes positioning the needle 102 inside the interior chamber of the organ 106 such that the antenna 130 substantially matches the shape and/or angular position of the wall to be ablated. By way of example, the position may place the antenna substantially parallel to the interior surface of the penetrated wall and proximate the targeted tissue. Furthermore, the method includes generating a microwave field at the antenna that is sufficiently strong to cause tissue ablation within the generated microwave field.

Although only a few embodiments of the present invention have been described in detail, it should be understood that the present invention may be embodied in many other specific forms without departing from the spirit or scope of the invention. Particularly, the invention has been described in terms of a microwave ablation assembly for cardiac applications. However, it should be appreciated that the present invention could be used for a wide variety of alternative applications as well. By way of example, the present invention may be used in most procedures relating to the ablation of internal biological tissues, and more particularly, to the ablation of organs with cavities such as the heart, the stomach, the intestines and the like. Further, although the described assembly works extremely well for microwave applications, it may be used to transmit electromagnetic energy at other frequencies as well, for example, radio frequencies. Additionally, it is contemplated that the present invention may be practiced with other suitable ablative energy sources. By way of

example, the present invention may be practiced with electrical current, ultrasound, electrical pulses, cryotherapy, lasers, and the like. In such configurations, the ablation element may be one or several metallic electrodes, a laser transducer, a cryogenic transducer, or an ultrasound transducer, while the transmission element may be a metallic wire, a fiber optic or a tube carrying cooling fluid.

Furthermore, while the invention has been described in terms of several preferred embodiments, there are alterations, permutations, and equivalents, which fall within the scope of this invention. By way of example, the ablation assembly may also include a series of mapping electrodes to detect electrophysiological signals from the cardiac tissue. Such electrodes can be used to map the relevant region of the heart prior to or after an ablation procedure. The electrodes may also be used to monitor the patient's condition and/or the nature of the ablation process. The electrodes may be disposed along the antenna device in the antenna region, along the transmission line, or along the clamping finger. The electrode bands may optionally be divided into a plurality of electrically isolated electrode segments. The information obtained from the electrodes is transmitted via electrode wires to external electronics such as an EP signal monitoring device. Filtering of the signal may be provided as necessary. In alternative embodiments, some of the external electronics could be incorporated into the power supply and/or the power supply could use information obtained from the electrodes in its control scheme.

In addition, the ablation assembly may also include a series of thermometry elements for measuring the temperature of the tissue. The thermometry elements may take the form of thermocouple wires, fiber optic sensor cables or any other suitable thermometry devices. The thermometry elements may be disposed along the antenna device, along the transmission line, or along the clamping finger.

Moreover, although the ground plane has been shown and described as being directly connected to the outer conductor of the transmission line, it may be indirectly grounded through an external conductor. This type of arrangement also creates a more intense electromagnetic field, but not to the same degree as the directly connected ground plane.

Further, it is also contemplated that the ablation assembly may be widely modified without departing from the scope of this invention. By way of example, balloons may be positioned at the inner or outer penetration of the organ to seal the puncture site. Additionally, the ablation assembly may include a chemical delivery system for injecting chemical agents into the penetrated tissue. Further still, purse string sutures may be used to help seal the puncture site of the organ. It should also be noted that there are many ways of implementing the methods and apparatuses of the present invention. It is therefore intended that the following appended claims be interpreted as including all such alterations, permutations, and equivalents as fall within the true spirit and scope of the present invention.
